Predicting ecosystem stability from community composition and biodiversity

de Mazancourt, Claire ; Isbell, Forest ; Larocque, Allen ; Berendse, Frank ; De Luca, Enrica ; Grace, James B ; Haegeman, Bart ; Polley, H Wayne ; Roscher, Christiane ; Schmid, Bernhard ; Tilman, David ; van Ruijven, Jasper ; Weigelt, Alexandra ; Wilsey, Brian J ; Loreau, Michel

Abstract: As biodiversity is declining at an unprecedented rate, an important current scientific challenge is to understand and predict the consequences of biodiversity loss. Here we develop a theory that predicts the temporal variability of community biomass from the properties of individual component species in monoculture. Our theory shows that biodiversity stabilises ecosystems through three main mechanisms: (1) asynchrony in species' responses to environmental fluctuations, (2) reduced demographic stochasticity due to overyielding in species mixtures, and (3) reduced observation error (including spatial and sampling variability). Parameterized with empirical data from four long-term grassland biodiversity experiments, our prediction explained 22–75% of the observed variability, and captured much of the effect of species richness. Richness stabilized communities mainly by increasing community biomass and reducing the strength of demographic stochasticity. Our approach calls for a re-evaluation of the mechanisms explaining the effects of biodiversity on ecosystem stability.

Short running title: Predicting ecosystem stability

Keywords: biodiversity, stability, prediction, environmental stochasticity, demographic stochasticity, overyielding

Type of article: Letter; **Number of words in the abstract:** 144; **Number of words in total:** 7,184; **Number of words in main text:** 4,973; **Number of references:** 46; **Figures and tables:** 5 figures and 1 table.

Author contributions: CdM and ML designed and analysed the theoretical model, with help from BH. CdM performed the simulations, derived the approximation and method for parameter estimation, with help from ML, BH, BS and FI. FB, EDL, HWP, CR, BS, DT, JvR, AW and BJW provided, and FI and AL analysed the data. JBG performed structural equation modeling. All authors contributed to writing the manuscript.

40 **Abstract**

41 As biodiversity is declining at an unprecedented rate, an important current scientific
42 challenge is to understand and predict the consequences of biodiversity loss. Here we
43 develop a theory that predicts the temporal variability of community biomass from the
44 properties of individual component species in monoculture. Our theory shows that
45 biodiversity stabilises ecosystems through three main mechanisms: (1) asynchrony in
46 species' responses to environmental fluctuations, (2) reduced demographic stochasticity due
47 to overyielding in species mixtures, and (3) reduced observation error (including spatial and
48 sampling variability). Parameterized with empirical data from four long-term grassland
49 biodiversity experiments, our prediction explained 22–75% of the observed variability, and
50 captured much of the effect of species richness. Richness stabilized communities mainly by
51 increasing community biomass and reducing the strength of demographic stochasticity. Our
52 approach calls for a re-evaluation of the mechanisms explaining the effects of biodiversity on
53 ecosystem stability.

54

55 **Introduction**

56 Ecosystems are subject to temporal variations in environmental conditions and various
 57 stressors, and an important aspect of their functioning is their temporal stability in response
 58 to these extrinsic factors. The intuitive idea that biodiversity allows different species to
 59 compensate for each other and thereby stabilises communities and ecosystems (MacArthur
 60 1955; Elton 1958) was challenged by theoretical work in the 1970's (May 1973), leading to a
 61 long-standing debate on the relationship between diversity and stability in ecology
 62 (McNaughton 1977; McCann 2000; Ives & Carpenter 2007; Loreau 2010, p. 124). This
 63 debate can be partly resolved by the fact that diversity often has a dual effect on stability: it
 64 stabilises total community biomass, while at the same time destabilising individual species
 65 abundances (Tilman 1996; Tilman *et al.* 2006; Roscher *et al.* 2011). Many experiments have
 66 confirmed the stabilising effects of biodiversity on ecosystem properties (Hooper *et al.* 2005;
 67 Tilman *et al.* 2006; van Ruijven & Berendse 2007; Isbell *et al.* 2009; Hector *et al.* 2010;
 68 Proulx *et al.* 2010; Allan *et al.* 2011).

69 A number of theories have been developed recently to explain the stabilising effect of
 70 diversity on aggregate ecosystem properties. These theories have followed four main
 71 approaches (Loreau 2010, p. 128): (1) a statistical approach based on the phenomenological
 72 mean–variance scaling relationship, which considers neither population dynamics nor species
 73 interactions explicitly but which is easily applied to empirical data (Doak *et al.* 1998; Tilman
 74 1999); (2) a stochastic, dynamical approach that describes population dynamical responses to
 75 environmental fluctuations but does not explicitly consider species interactions (Yachi &
 76 Loreau 1999); (3) a general population dynamical approach that includes a deterministic
 77 component describing species interactions and a stochastic component describing
 78 environmental fluctuations (Hughes & Roughgarden 1998; Ives *et al.* 1999; Hughes &
 79 Roughgarden 2000; Ives & Hughes 2002); and (4) specific models of interspecific

competition in which tradeoffs lead to coexistence (Tilman 1999; Lehman & Tilman 2000). Although each of these approaches sheds some light on the effects of species diversity on ecosystem stability, the underlying mechanisms that drive these effects have not been elucidated and remain contentious (Loreau 2010, ch. 5). So far, none of these approaches has been able to predict ecosystem stability from the properties of component species.

Here we expand previous theory following the population dynamical approach (Ives *et al.* 1999; Lehman & Tilman 2000; Loreau & de Mazancourt 2008) to more realistic communities in which species are affected by a combination of intra- and interspecific competition, environmental stochasticity and demographic stochasticity, and in which they differ in all their parameters. We use this new theory to generate a prediction of ecosystem stability that is derived from the properties of individual species in monoculture and that can be applied to mixed communities. We then test our theoretical prediction with the results of four long-term grassland biodiversity experiments in which species richness was manipulated, and we discuss how it can elucidate the mechanisms that drive the effects of diversity, in particular species richness, on ecosystem stability.

Theoretical Model

Materials and Methods

Our theoretical model is based on a discrete-time version of the classical Lotka–Volterra model that incorporates environmental and demographic stochasticity (Ives *et al.* 1999; Loreau & de Mazancourt 2008):

$$\tilde{r}_i(t) = \ln \tilde{N}_i(t+1) - \ln \tilde{N}_i(t) = r_{mi} \left[1 - \frac{\tilde{N}_i(t) + \sum_{j \neq i} \alpha_{ij} \tilde{N}_j(t)}{K_i} \right] + \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{\tilde{N}_i(t)}}, \quad (1)$$

101 where $\tilde{N}_i(t)$ is the biomass of species i in year t , and $\tilde{r}_i(t)$ is its instantaneous mass-specific
 102 growth rate in year t . A tilde denotes the real, unknown quantities, as observed biomass and
 103 growth rate are affected by observation error (see below). r_{mi} is species i 's intrinsic
 104 (maximum) rate of natural increase, K_i is its carrying capacity, and α_{ij} is the interspecific
 105 competition coefficient describing the effect of species j on species i . Environmental
 106 stochasticity describes a year effect on a species' growth rate. It is incorporated through
 107 $\sigma_{ei}u_{ei}(t)$, where σ_{ei}^2 is the environmental variance, and $u_{ei}(t)$ are normal variables with zero
 108 mean and unit variance that are independent through time (white noise) but may be correlated
 109 between species (e.g. a good year for one species may be good for another species as well).
 110 Demographic stochasticity is the last term in equation (1). It is due to variation in birth and
 111 death rates between individuals or independent reproductive units. Here we incorporate it in
 112 the form of the first-order, normal approximation that is traditionally used in the theory of
 113 stochastic population dynamics (Lande *et al.* 2003) to facilitate mathematical analysis.
 114 Individuals are not well defined in grassland plants and the number of individuals (such as
 115 the number of genets) is a poor descriptor of plant population dynamics. The number relevant
 116 for population dynamics is the number of plant modules, defined as demographic plant units
 117 with a high functional independence (e.g. tillers, shoots or rosettes, Schmid 1990). Module
 118 density is quite strongly correlated with biomass (Marquard *et al.* 2009), which is why we
 119 use biomass rather than number of individuals. σ_{di}^2 is the demographic variance, and $u_{di}(t)$
 120 are independent normal variables with zero mean and unit variance. The observed biomass of
 121 species i in year t , $N_i(t)$, is estimated through a sampling procedure that generates an
 122 observation error due to factors such as spatial heterogeneity and variability in sample
 123 collection and sorting. Observed biomass is the real biomass plus a random variable

representing observation error on a log scale, $\sigma_{oi} \overline{u_{oi}(t)}$ (Ives *et al.* 2003), where σ_{oi}^2 is the observation variance, and $\overline{u_{oi}(t)}$ is the average of independent normal variables with zero mean and unit variance across the subsamples taken in a plot in year t :

$$\ln(N_i(t)) = \ln(\tilde{N}_i(t)) + \sigma_{oi} \overline{u_{oi}(t)}. \quad (2)$$

Community biomass is defined as the sum of the biomasses of component species. We use our model to derive an analytical prediction of the temporal coefficient of variation of community biomass, as this inverse measure of ecosystem stability has been commonly used in experiments (Tilman *et al.* 2006; Ives & Carpenter 2007; van Ruijven & Berendse 2007; Isbell *et al.* 2009; Proulx *et al.* 2010; Allan *et al.* 2011). The derivation proceeds as follows. First, we compute the deterministic equilibrium values of model (1) in the absence of any stochasticity. Second, we assume that the system reaches a stationary state, and we linearise equations (1) and (2) around the equilibrium by representing all forms of stochasticity as additive Gaussian variables. Third, we derive an analytical prediction of the variance-covariance matrix of component species biomasses. Fourth, we obtain the variance of community biomass as the sum of the variances and covariances of component species biomasses, from which we obtain the coefficient of variation of community biomass (see more details in online supporting information, section A).

The analytical predictions of the observed variance and coefficient of variation (CV) of community biomass at stationary state should hold as a first-order, linear approximation for any more realistic model (online supporting information, section A). This approximation, however, is impractical because estimating the large number of pairwise competition coefficients between species would require longer time-series than available. Given the data limitations, we make the simplifying assumption that interspecific competition affects only

the mean abundances of species, not their year-to-year dynamics, i.e., the abundance of species in a given year does not predict its effect on competitors in the following year (online supporting information, section A). This simplifying assumption allows us to derive a simple theoretical prediction for the CV of community biomass that can be parameterised using existing experimental data. Our prediction can be seen as a first, coarse approximation; longer time-series would be required to estimate competitive effects. If competitive effects could be estimated, the full first-order approximation could be computed by solving equation (A11). Below we test our prediction against simulations where species differ in all their parameters, with high and asymmetric competition.

Results

Our prediction is:

$$CV_{NT}^2 = \left(\frac{\sigma_{NT}}{N_T} \right)^2 \approx \varphi_e \Sigma_e^2 + \frac{\Sigma_d^2}{N_T} + \lambda \frac{\Sigma_o^2}{n_x}. \quad (3)$$

In this equation, φ_e is a measure of the synchrony of species environmental responses, where species environmental responses are species-specific properties independent of species interactions and measured by the year effect on their growth rate in monocultures; synchrony is then computed from the variance-covariance matrix of these environmental responses. Σ_e^2 is the mean scaled environmental variance, Σ_d^2 is the mean scaled demographic variance, $\overline{N_T}$ is mean community biomass, λ is Simpson's (1949) concentration index (a measure of dominance), n_x is the number of subsamples taken within a plot and year used to estimate the CV of community biomass, and Σ_o^2 is the mean observation variance (online supporting information, section A, equations A22–A26).

Equation (3) comprises three additive terms, which encapsulate the respective influences of environmental stochasticity, demographic stochasticity, and observation error

on variability of total biomass. The mean scaled environmental, mean scaled demographic, and mean observation variances are weighted means of individual-level variances. As such they can be affected by differences in community composition and species relative abundances across plots. However, there should be no systematic effect of species diversity on these variances unless there is selection for species with high or low variances in mixtures (Loreau and Hector 2001). Equation (3) then suggests three main mechanisms through which species diversity can stabilise community biomass: (1) by decreasing the synchrony of species environmental responses, φ_e , which dampens the effect of environmental stochasticity at the community level through functional compensation between species (Gonzalez & Loreau 2009; Loreau 2010, p. 130); this mechanism underlies the insurance hypothesis; (2) by increasing community biomass, N_T , which increases the number of demographic modules and thereby reduces the strength of demographic stochasticity at the community level; and (3) by decreasing Simpson's concentration index, λ , which reduces the impact of observation error at the community level. Observation error probably results mainly from spatial heterogeneity and sampling variability, whose effects tend to average out at the community level.

Numerical Simulations

Materials and Methods

We first tested the accuracy of our simplified analytical prediction (3) with numerical simulations of model (1) in which species differed in all their parameters and there was no observation error. In the simulations we considered four cases by varying two factors: (1) the

relative strength of environmental stochasticity versus demographic stochasticity (two levels, in which species demographic and environmental standard deviations were drawn from different ranges), and (2) connectance, i.e. the proportion of species competing with each other (two levels). In low-connectance communities, coexistence was ensured by setting most competition coefficients to zero, resulting in low levels of interspecific competition overall. In high-connectance communities, all species competed with each other and coexistence was ensured by a low variability among competition coefficients scaled (divided) by relative carrying capacities (Jansen & Kokkoris 2003), resulting in higher levels of interspecific competition than in low-connectance communities.

For numerical simulations, we drew parameters from random distributions to generate stable coexisting communities at 6 species richness levels ($S = 1, 2, 4, 8, 16, 32$) and 11 target values of the synchrony of species environmental responses, φ_e , as our analysis above shows that this is a key factor that affects ecosystem stability. Our measure of synchrony is bounded between 0 (perfect asynchrony) and 1 (perfect synchrony). Community dynamics was simulated for 2,010 time-steps, and realised communities were those where none of the species went extinct during the simulation. The last 10 time-steps ensured that no species was on the brink of extinction at the end of the time-series, and time-steps 1,000–2,000 were used to estimate the characteristics of the community and of its component species. We simulated 1,000 single-species communities. For each of the other values of species richness, we generated 200 realised communities for each target level of species synchrony of environmental response (11 values regularly spaced between 0 and 1). We repeated the simulations for 2 levels of connectance and 2 levels of environmental and demographic variances. More details are provided in online supporting information, section B1.

Results

Numerical simulations strongly supported our analytical prediction at low levels of connectance as there was an excellent match between the prediction and the realised CV of community biomass at all levels of species diversity (Fig. 1, left panels). At high levels of connectance and interspecific competition, the match was still present but was less strong (Fig. 1, right panels). Recall that our prediction includes the effect of interspecific competition on average species abundances, but not its effect on year-to-year dynamics. Although the strength of interspecific competition should not affect community variability when communities are symmetrical (Ives *et al.* 2000; Loreau 2010, p. 150), it does when species differ (Fowler 2009; Loreau & de Mazancourt in press). Our prediction then tends to underestimate community variability, suggesting that asymmetric competition tends to destabilise communities (Loreau & de Mazancourt in press).

Our theory predicts that the relative importance of the various stabilising mechanisms at work depends on the relative strengths of environmental stochasticity, demographic stochasticity, and observation error because the three terms are additive (equation 3). When environmental stochasticity is the dominant force driving community dynamics, asynchrony between species environmental responses (mechanism 1 above) is responsible for the stabilising effect of diversity (Fig. S1, top panels). In contrast, when demographic stochasticity dominates, diversity affects stability through its effect on community biomass (mechanism 2 above; Fig. S2, bottom panels).

Application to Field Data

Materials and Methods

One attractive feature of our approach is that it can be applied directly to empirical data. All species-specific parameters, such as their intrinsic rate of natural increase, carrying capacity,

environmental response through time, and demographic variance, can be estimated using replicated monoculture time-series for each species. Observation variance requires measurements of several samples within monoculture plots. The only information needed from mixtures is the time-average of the abundance of each component species (online supporting information, section B3). Equation (3) can then be used to predict the variability of community biomass in mixtures from independent data.

We used data from four long-term grassland biodiversity experiments in Cedar Creek (Minnesota, USA), Jena (Germany), Texas (USA) and Wageningen (The Netherlands) to assess the extent to which our prediction matched the observed temporal variation of community biomass (online supporting information, section B2-B4). In all experiments, diversity treatments were maintained for at least 8 years through hand-weeding programs. More details are provided in online supporting information, section B2 and summarized in Table S1.

For each data set, species parameters were estimated for each species independently, using time-series analysis of log biomass and growth rates in replicated monocultures. Several samples within monoculture plots were taken in Cedar Creek and Jena; observation variance could thus be estimated for these two experiments. Parameters from component species were then combined into the components of our prediction (equation 3), with weightings depending on their mean abundance in mixture (online supporting information equations A22-A26). Details are provided in online supporting information, section B3. Major axis regression was performed where explanatory variables were estimated, with the lmodel2 package in R 2.11.1 (see online supporting information, section B4).

To understand the importance of the different mechanisms in predicting community variability and the effect of species richness, we developed two sets of structural equation models (online supporting information, section B5). Structural equation modeling allows

evaluation of complex causal hypotheses by translating a set of hypothesized causal relationships into a pattern of expected statistical relationships in the data (Grace 2006). The first set of models simply related observed variability to the three additive components of our prediction, demographic stochasticity, environmental stochasticity, and observation error, for the four data sets (Fig. 3). The second set of models was designed to address the more complex question of how each of the six individual components of equation (3) contributed to the overall effect of species richness on variability in community biomass (Fig. 3).

Results

Across the four data sets, our prediction explained 22–75% of the variance in the observed CV of aboveground community biomass (Fig. 2). Our prediction fared in a similar way than species richness in Cedar Creek, Wageningen and Jena, and much better in Texas (Table 1). When the two variables were fitted together, both variables were significant (Table 1). The explanatory power, compared to our prediction alone, increased minimally with the addition of species richness in Cedar Creek and Texas, and moderately so in Wageningen and Jena (Table 1). Regression lines between observed CV of aboveground biomass and our prediction were often away from the 1:1 line.

To understand how the three additive components of our prediction (equation 3) contribute to its explanatory power, we modeled their respective effects on observed variability using structural equation modeling (Fig. 4). In this analysis, the three components were treated as equal and separate (though intercorrelated) predictors. Since the intercorrelation strengths among them were modest (0.06–0.34), it is possible to interpret the standardized path coefficients, which technically represent predicted sensitivities, as measures of their relative importance. Demographic stochasticity was the most important component in three experiments (Wageningen, Jena and Texas); environmental stochasticity

also made a significant contribution in these experiments (Fig. 4). Unexpectedly, predicted observation error was the most important component at Cedar Creek. This effect of observation error is confirmed by a direct fit of measured observation error on the observed CV of community biomass, which was also significant (Cedar Creek, $R^2=0.1$, $p<0.001$; Jena $R^2=0.18$, $p<0.001$). Correlations among components were generally positive. A negative correlation between demographic and environmental stochasticities was observed for Cedar Creek (Fig. 4).

Next, we used structural equation modeling to investigate which components of equation (3) were likely to have contributed to the stabilising effect of species richness on community biomass. We first consider the effect of species richness on each component. Theory predicts that synchrony of species environmental responses, mean community biomass and Simpson's concentration index should be affected by species diversity, and they always were (Fig. 5). The mean scaled environmental, scaled demographic and observation variances represent weighted means of individual-level variances; they depend on community composition and species relative abundances but we expect no systematic effect of species richness on these variances unless there is selection for species with either high or low variances in mixtures. These variances were indeed not affected by species richness most of the time, with three exceptions: demographic variance increased with species richness in Cedar Creek and Texas, and observation variance increased with species richness in Cedar Creek. There was thus a selection effect for more variable species in these two experiments.

The effect of species richness on community variability was mediated through community biomass in all experiments (Fig. 5). Additional effects of species richness were observed directly (in Wageningen) or through variables that are highly correlated with species richness, such as Simpson's concentration index (in Cedar Creek and Jena), or

synchrony (Texas). In both Cedar Creek and Texas, the stabilising effect of diversity was slightly counter-acted by a selection effect for species with higher demographic variances.

The first stabilisation mechanism we identified is reduced environmental stochasticity at the community level because of differences between species' responses to environmental fluctuations, which generate decreased synchrony φ_e with increased diversity. A strong negative effect of species richness on the synchrony of species environmental responses was found in all four experiments (Fig. 5). Surprisingly, the significant effect of species richness on the synchrony of species environmental responses (φ_e) only seemed to make a significant contribution to community stability in Texas (Fig. 5).

The second mechanism is reduced demographic stochasticity at the community level because of increased community biomass with higher diversity. In all four experiments, more diverse communities had a higher mean community biomass (Fig. 5). This second stabilisation mechanism is likely to have played a significant role in all four experiments, where community biomass made a significant contribution to community stability. However, in Cedar Creek and Texas, this was slightly counteracted by a selection effect of more variable species (Fig. 5). This is shown by the positive effect of species richness on demographic variance, which in turn results in higher community variability.

Finally, we predicted a possible effect of diversity on community stability through reduced observation error. This seemed to be the case in the two experiments in which multiple samples per plot were taken, i.e., Cedar Creek and Jena (Fig. 4), where the effect was mediated through Simpson's concentration index (Fig. 5). In both experiments, the predicted observation error was significantly correlated with its observed value (Online Supporting Information, Fig. S3). Species richness also slightly affected the measured observation error (Cedar Creek: $R^2 = 0.08$, $P < 0.001$; Jena: $R^2 = 0.02$, $P < 0.05$). Thus,

observation error is likely to have played a minor role in the positive relationships between biodiversity and stability in these experiments.

Discussion

The theory we have developed here makes three major contributions: first, it clarifies the nature of a number of stabilising mechanisms and how they interact to drive ecosystem stability; second, for the first time it provides a way to disentangle them quantitatively in field biodiversity experiments; and third, it provides the first prediction of the stability of aggregate ecosystem properties from the properties of individual species. Our theoretical prediction encapsulated in equation (3) explained 22–75% of the variance in the observed variability of aboveground community biomass in four long-term grassland biodiversity experiments. The percent of variance explained by our prediction was similar to that explained by planted species richness alone, except in Texas where it was much better (Table 1). Adding species richness to a model with our prediction improved explanatory power little in two experiments (Cedar Creek and Texas), and moderately in two locations (Jena and Wageningen) (Table 1). This suggests that the mechanisms captured in our prediction cover a good part of the effects of species richness on community variability. Our prediction also includes some effects of total plot biomass, evenness and species identity that come into play in the various terms of equation (3). Although our prediction was correlated with the observed CV, it could be further improved to increase its predictive ability.

Note that a correlation between our prediction and the observed CV could be expected for monocultures since both are estimated from the same data. However, correlations remained highly significant when monocultures were removed from the analysis, except in Wageningen where it became non significant (results not shown). Many different factors

could account for the lower range of explanatory power of our theoretical prediction. First, time series are short (in terms of time-series analysis), and there is a relatively low number of monocultures. Accuracy in parameter estimation is therefore limited, especially because field data are very variable. Second, our prediction assumes that the abundance of species in a given year does not affect their competitors the following year. As discussed previously, longer time-series would be required to obtain reliable estimates of yearly competition effects, and a better prediction using estimated competition coefficients could be compiled solving equation (A11). Third, our prediction relies on a first-order, linear approximation of yearly competitive effects and stochasticity terms; it assumes that perturbations are small – which they are not, and that interactions between these various factors are negligible, or in other words, that the behaviour in monoculture reflects the behaviour in mixture. Finally, experiments are probably far from the steady-state assumed.

Our theory predicts that three main mechanisms underlie the stabilising effect of species richness on community biomass in biodiversity experiments. The first mechanism, asynchrony of species environmental responses, is predicted to be important when environmental stochasticity plays a significant role in community variability (Fig. S1, top row). The strong negative correlation between the synchrony of species environmental responses and species richness in all four experiments (Fig. 5) shows that this stabilisation mechanism is potentially strong. This potential, however, seemed to be realised only in Texas, the only experiment where synchrony of species environmental responses made a significant contribution to community variability (Fig. 5). The relatively short length of the experiments (8–13 years) and variability between plots may also have restricted our ability to detect significant environmental signals in the data.

Note that a species' environmental response is an intrinsic species-specific property that defines its functional response type or trait (Diaz & Cabido 2001); it is measured by the year effect on growth in monoculture, in the absence of interspecific interactions. It can also be estimated from natural systems with replicated time series (Mutshinda *et al.* 2009; Thibaut *et al.* 2012). By contrast, population fluctuations result from many different processes, including species responses to the environment, density dependence, species interactions, and demographic stochasticity. Therefore asynchrony in species environmental responses must be carefully distinguished from asynchrony in population fluctuations (Loreau & de Mazancourt 2008). In particular, asynchrony in species environmental responses cannot be measured by the summed covariances of population fluctuations. Summed species covariances are strongly affected by species interactions such as competition, and can be negative even when competition acts to decrease community stability (Loreau & de Mazancourt in press). Therefore summed species covariances are unlikely to provide a mechanistic explanation for community stability. In contrast, asynchrony of species environmental responses is a measure of functional response diversity (Diaz & Cabido 2001); it is the basic mechanism of the insurance hypothesis (Ives *et al.* 1999; Yachi & Loreau 1999). It is also the likely cause of the stabilising effect of diversity on community biomass in resource competition models (Tilman 1999; Lehman & Tilman 2000). In these models, the interspecific tradeoffs that generate coexistence, such as species having different optimal temperatures, also cause species to have asynchronous responses to environmental (temperature) fluctuations. Our theory highlights asynchrony of species environmental responses as a mechanism that drives the stabilising effect of species diversity on aggregate ecosystem properties, a mechanism that is more closely related to the concept of functional compensation as initially envisaged by ecosystem ecologists (McNaughton 1977). Thibaut *et al.* (2012) found that this was likely the main mechanism driving the diversity-stability relationship in coral reefs communities. We suggest that future research on compensatory dynamics would benefit from focusing on

408 asynchrony of species environmental responses rather than on mere patterns of population
 409 fluctuations (Loreau 2010, ch. 5).

410 The second mechanism our theory highlights, reduced demographic stochasticity with
 411 increased community biomass, is predicted to be important when demographic stochasticity
 412 is a significant driver of community variability (Fig. S2, bottom row). Species richness
 413 increases community biomass through functional complementarity between species and/or
 414 through selection of more productive species, a phenomenon known as overyielding (Loreau
 415 & Hector 2001). A positive effect of species richness on community stability through
 416 community biomass was found in all four experiments (Fig. 5). This stabilisation mechanism
 417 played a role in all four experiments, although it was slightly counteracted by a selection
 418 effect for more variable species in Cedar Creek and Texas (Fig. 5).

419 Our analysis provides a mechanistic underpinning for the stabilising effect of
 420 community biomass. Previous arguments were based on empirical scaling relationships
 421 between the mean and the variance of species abundances with the form $\sigma_{ni}^2 = an_i^z$, where z
 422 is a scaling coefficient typically between 1 and 2 (Taylor & Woivod 1982). Two known
 423 mechanisms create such a scaling coefficient for individual species: demographic
 424 stochasticity (Anderson *et al.* 1982), and competitive interactions between species (Kilpatrick
 425 & Ives 2003). Both mechanisms were at work in our model, although only demographic
 426 stochasticity results in a stabilisation of diverse communities through overyielding. We
 427 suggest that future research would benefit from exploring the role of demographic
 428 stochasticity to explain ecosystem stability.

429 Finally, our theory also predicts a potential effect of diversity on ecosystem stability
 430 through reduced observation error. This effect comes from the assumption that the biomasses
 431 of different species are measured independently. The higher the diversity, the more the

observation errors on species biomass average out in community biomass. Common species contribute more to community biomass variability than rare species, with the appropriate weighting being given by Simpson's index. Observed observation error decreased slightly with species richness in the field, although the R^2 were small (results section). Is reduced observation error a genuine stabilisation mechanism or just a methodological problem? We suspect that a significant part of measurement error comes from spatial heterogeneity. If biodiversity decreases spatial heterogeneity at the community level by averaging out heterogeneity of the component species, then it can be considered a genuine mechanism through which diversity stabilises communities. This mechanism was likely to play a role in the Cedar Creek and Jena experiments (Fig. 4 and 5). Although reduced observation error may be viewed as a statistical mechanism due to sampling constraints rather than as a genuine ecological mechanism, its influence on the results of biodiversity experiments should not be ignored. Observation error, which has been overlooked so far, will be important to consider explicitly in future biodiversity experiments.

What is the role of competition in stabilising communities? Interspecific competition is often hypothesised to stabilise communities through compensatory dynamics. However, mathematical exploration of the full community dynamics, obtained by solving equation (A11) for a 2-species community with interspecific competition, shows that interspecific competition can have dual effects, but that it most often has a destabilising effect at both the population and community levels (Loreau & de Mazancourt in press). Some recent studies suggest that interspecific interactions contribute little to community stability in a range of animal taxa (Mutshinda *et al.* 2009; Almaraz *et al.* 2012; Thibaut *et al.* 2012). Although our prediction encompasses the effect of interspecific competition on average abundance, it

ignores its potential effects on year-to-year dynamics. Longer time-series will be necessary to assess the importance of year-to-year interspecific competitive interactions in experimental plant communities.

Our work provides a new predictive theory of the stability of community biomass that can be parameterised from species-specific properties obtained independently, and their abundance in mixture. To be estimated, our prediction requires experimental data from monocultures, but given enough temporal and spatial resolution, parameters could in principle be estimated from natural communities (as in Almaraz *et al.* 2012; Thibaut *et al.* 2012). Thus our approach offers the potential for understanding and predicting the stability of an important ecosystem service in the face of biodiversity loss and other environmental changes from knowledge of individual species responses to these changes. This could provide a useful tool to inform policy and economic decision-making processes about the insurance value of biodiversity in the provision of ecosystem services (Baumgärtner 2007).

592 **explained by our prediction alone** (equation 3), **planted or sown species richness alone,**
593 **and both variables** on a log scale: $\log(\text{observed CV}) \sim \log(\text{term})$. Stars indicate level of
594 significance: *** $p < 0.001$, ** $p < 0.01$. Note that for each site, the model including the whole
595 prediction only has the same number of degrees of freedom as the model with species
596 richness only: both have one single, continuous explanatory variable. Statistics for the full
597 model (whole prediction + species richness) are presented in Appendix Table S3.

598

Figure 1 | The coefficient of variation (CV) of community biomass is well explained by the prediction in simulated model communities. Left column: low connectance (low competition) communities; right column: high connectance (high competition) communities. Either environmental stochasticity (top row) or demographic stochasticity (bottom row) is the main driver of community variability. Each dot represents one community, colour indicates species richness. A sample of 1,200 out of the 12,000 simulated communities was plotted for clarity. Dashed black line represents the 1:1 line. Coloured solid lines represent the regression lines for each corresponding level of species richness. Black solid line is the regression line pooling all levels of species richness together, regression whose R^2 is shown.

Figure 2 | The observed coefficient of variation (CV) of community biomass in the four experiments was relatively well predicted by the prediction. R^2 and P -values are for major-axis regressions (supplementary information section B4). Black dashed lines indicate 1:1 relationship. Grey lines indicate 95% confidence interval for slope. Colours indicate the number of planted or sown species.

Figure 3 | Decomposing equation 3 for structural equation modelling. In the first set of structural equation models (Fig. 4), the prediction was decomposed into three additive terms, i.e. environmental (orange), demographic (green) and observation (blue) terms. In the second set of structural equation models (Fig. 5), it was decomposed into the six components shown below the equation.

Figure 4 | SEM standardized results showing the contribution of each of the three terms of our prediction (Fig. 3) to the observed coefficient of variation of community biomass (Obs. CV). Env. term: environmental stochasticity term $\varphi_e \Sigma_e^2$; Dem. term: demographic stochasticity term $\frac{\Sigma_d^2}{N_T}$; Obs. term: observation error term $\lambda \frac{\Sigma_o^2}{n_x}$. There is no estimate for observation error in Wageningen and Texas, where samples are always taken at the same

place and represent the quasi-totality or the totality of plots; therefore there is no error due to partial sampling and spatial heterogeneity. Standardized path coefficients represent predicted sensitivities, i.e., what the predicted responses would be if an individual predictor were varied while the other variables in the model were held constant (Grace & Bollen 2005).

Figure 5 | Structural Equation Modeling standardized results showing how **planted or sown species richness** (Sp. richness) **affected the observed CV** (coefficient of variation of community biomass, Obs. CV) **through each of the six components of our prediction** (Fig. 3). Sync: synchrony of species environmental responses φ_e ; env var: mean scaled environmental variance Σ_e^2 ; com bio: mean community biomass $\overline{N_T}$; dem var: mean scaled demographic variance Σ_d^2 ; Simp: Simpson's (1949) concentration index, λ ; obs var: mean observation variance Σ_o^2 . A. Derivation of the prediction for the squared coefficient of variation of total community biomass (equation 3)

We first derive an analytical prediction for the variance of total community biomass in stationary state. To obtain it, we make a number of assumptions along the way, which we summarize here:

- The system has reached a stationary state with small perturbations around the deterministic equilibrium; therefore, a linear approximation around the equilibrium is sufficient.
- All stochastic components are Gaussian variables, with no temporal (environmental, demographic and observation) and spatial (demographic and observation) autocorrelations (white noise). For each species, the environmental responses are the same across all plots (response to a year effect); environmental responses can be correlated across species (a good year for one species might be a good year for another species). Demographic stochasticity is independent between species and plots. Observation errors are independent between species and samples within plots.
- Interactions between species do not affect their environmental responses, nor the magnitude of demographic stochasticity and observation error.
- The overall effect of competition on community stability is small, even if its effect on community biomass, composition and on individual species dynamics might be strong. Accordingly, we assume that competition coefficients are zero, but that species carrying capacities in communities are their observed abundances in communities.

Substituting equation (2) into equation (1), we get the following equation for the observed biomasses:

$$N_i(t+1) = N_i(t) \exp \left\{ r_{mi} \left[1 - \frac{N_i(t) + \sum_{j \neq i} \alpha_{ij} N_j(t)}{K_i} \right] + \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{N_i(t)}} \right. \\ \left. + \sigma_{oi} [\overline{u_{oi}(t+1)} - \overline{u_{oi}(t)}] + r_{mi} \left[\frac{N_i(t) \sigma_{oi} \overline{u_{oi}(t)} + \sum_{j \neq i} \alpha_{ij} N_j(t) \sigma_{oj} \overline{u_{oj}(t)}}{K_i} \right] \right\} \quad (A1)$$

First-order approximations of the temporal variance of total community biomass are obtained as follows (Ives 1995; Hughes & Roughgarden 2000; Ives & Hughes 2002; Loreau & de Mazancourt 2008). Let $\delta N_i(t) = N_i(t) - N_i^*$ denote the deviation of observed species i 's biomass from its equilibrium value in the community, N_i^* , in the absence of stochasticity. Equation (A1) can be Taylor expanded around $\delta N_i(t) = u_{ei}(t) = u_{di}(t) = u_{oi}^s(t) = 0$ to yield, after dropping terms of order two and higher,

$$\delta \mathbf{N}(t+1) = \mathbf{A} \delta \mathbf{N}(t) + \mathbf{z}(t), \quad (\text{A2})$$

where $\delta \mathbf{N}(t)$ is the vector of deviations of species biomasses from their deterministic equilibrium value, \mathbf{A} is the community matrix, also known as the Jacobian matrix around the equilibrium, with elements $(a_{ij})_{1 \leq i, j \leq S}$:

$$a_{ij} = \begin{cases} 1 - r_{mi} \frac{N_i^*}{K_i} & i = j \\ -r_{mi} \frac{N_i^*}{K_i} \alpha_{ij} & i \neq j \end{cases} \quad (\text{A3})$$

and $\mathbf{z}(t)$ is a vector that encapsulates the effects of environmental and demographic stochasticity as well as observation error, and whose elements are

$$z_i(t) = N_i^* \sigma_{ei} u_{ei}(t) + \sqrt{N_i^*} \sigma_{di} u_{di}(t) + N_i^* \sigma_{oi} [\overline{u_{oi}(t+1)} - \overline{u_{oi}(t)}] + \frac{r_{mi}}{K_i} \left(N_i^* \sigma_{oi} \overline{u_{oi}(t)} + \sum_{j \neq i} \alpha_{ij} N_j^* \sigma_{oj} \overline{u_{oj}(t)} \right) \quad (\text{A4})$$

When the system reaches a stationary distribution, the variances and covariances between species biomass time series are:

$$\langle \delta \mathbf{N}(t) \delta \mathbf{N}(t)^T \rangle = \mathbf{C}^\infty = (\text{cov}(N_i, N_j))_{1 \leq i, j \leq S} = (\text{cov}(\delta N_i, \delta N_j))_{1 \leq i, j \leq S} \quad (\text{A5})$$

where $\delta \mathbf{N}^T$ is the transpose of vector $\delta \mathbf{N}$, i.e. a row vector.

Since both $u_{oi}(t)$ and $u_{oi}(t-1)$ appear in $z_i(t)$, observation errors introduce a correlation between $\mathbf{z}(t-1)$ and $\mathbf{z}(t)$. Our assumptions listed above lead to the following correlation structure of \mathbf{z} :

$$\langle \mathbf{z}(t)\mathbf{z}(t)^T \rangle = \mathbf{Z}_0 \quad (\text{A6})$$

$$\langle \mathbf{z}(t-1)\mathbf{z}(t)^T \rangle = \mathbf{Z}_1 \quad (\text{A7})$$

$$\langle \mathbf{z}(t-s)\mathbf{z}(t)^T \rangle = 0 \quad \text{for } s > 1 \quad (\text{A8})$$

We use (A2) to write a dynamical equation for the covariance \mathbf{C} :

$$\begin{aligned} \mathbf{C}(t+1) &= \langle \delta \mathbf{N}(t+1) \delta \mathbf{N}(t+1)^T \rangle \\ &= \mathbf{A} \langle \delta \mathbf{N}(t) \delta \mathbf{N}(t)^T \rangle \mathbf{A}^T + \mathbf{A} \langle \delta \mathbf{N}(t) \mathbf{z}(t)^T \rangle + \langle \mathbf{z}(t) \delta \mathbf{N}(t)^T \rangle \mathbf{A}^T + \langle \mathbf{z}(t) \mathbf{z}(t)^T \rangle \\ &= \mathbf{A} \mathbf{C}(t) \mathbf{A}^T + \mathbf{A} \langle \delta \mathbf{N}(t) \mathbf{z}(t)^T \rangle + \langle \mathbf{z}(t) \delta \mathbf{N}(t)^T \rangle \mathbf{A}^T + \mathbf{Z}_0 \end{aligned} \quad (\text{A9})$$

Using (A2), (A7) and (A8), we obtain:

$$\begin{aligned} \langle \delta \mathbf{N}(t) \mathbf{z}(t)^T \rangle &= \mathbf{A} \langle \delta \mathbf{N}(t-1) \mathbf{z}(t)^T \rangle + \langle \mathbf{z}(t-1) \mathbf{z}(t)^T \rangle \\ &= 0 + \mathbf{Z}_1 \end{aligned} \quad (\text{A10})$$

Substituting into (A9), and taking the limit $t \rightarrow \infty$ on both sides, we get:

$$\mathbf{C}^\infty = \mathbf{A} \mathbf{C}^\infty \mathbf{A}^T + \mathbf{B} \quad (\text{A11})$$

where

$$\mathbf{B} = \mathbf{A} \mathbf{Z}_1 + \mathbf{Z}_1^T \mathbf{A}^T + \mathbf{Z}_0 \quad (\text{A12})$$

The variance of total community biomass, σ_{NT}^2 , is the sum of all the elements of the \mathbf{C} matrix. If all parameters are known, equation (A11) can be solved. However, solving it requires an estimate of all interspecific competition coefficients, which requires unrealistically long time-series (Ives *et al.* 2003). Because of data limitations, we have to make the simplifying assumption that competition does not affect the dynamics at the community level. Such assumption would be reasonable in symmetrical models where all

species have the same parameters, where competition does not affect the variance of total biomass (Ives *et al.* 1999; Loreau & de Mazancourt 2008). It would also be reasonable if the time-scale of operation of competition was much less than the sampling time-scale. In such case, the effect of competition on species biomass could be strong, but its effect would not be detected in a time-series analysis. This was demonstrated for density dependence in single-species dynamics (Doncaster 2008), and is consistent with time-series analyses that find little evidence for interspecific interactions using time-series data (Mutshinda *et al.* 2009). To apply our approach, we assume that interspecific competition has a strong effect on the average biomass of the species in the community, but that the effects of competition through year-to-year dynamics of the species have a small-enough overall effect on the stability of total community biomass. Accordingly, we set all interspecific competition coefficients to zero, and species carrying capacities to their average biomass in the community. The community matrix reduces to its diagonal elements, $a_i = 1 - r_{mi}$.

With this approximation, equation (A4) simplifies to:

$$z_i(t) = N_i^* \sigma_{ei} u_{ei}(t) + \sqrt{N_i^*} \sigma_{di} u_{di}(t) + N_i^* \sigma_{oi} [\overline{u_{oi}(t+1)} - (1 - r_{mi}) \overline{u_{oi}(t)}], \quad (\text{A13})$$

the elements of matrix \mathbf{Z}_0 (equation A6) are:

$$z_{ij}^0 = N_i^* N_j^* \sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}(t), u_{ej}(t)) + \sqrt{N_i^*} \sqrt{N_j^*} \sigma_{di} \sigma_{dj} \text{cov}(u_{di}(t), u_{dj}(t)) + [1 - (1 - r_{mi})(1 - r_{mj})] N_i^* N_j^* \sigma_{oi} \sigma_{oj} \text{cov}(\overline{u_{oi}(t)}, \overline{u_{oj}(t)}), \quad (\text{A14})$$

the elements of matrix \mathbf{Z}_1 (equation A7) are:

$$z_{ij}^1 = -(1 - r_{mj}) N_i^* N_j^* \sigma_{oi} \sigma_{oj} \text{cov}(\overline{u_{oi}(t)}, \overline{u_{oj}(t)}) , \quad (\text{A15})$$

and the elements of matrix \mathbf{B} (equation A12) are:

$$b_{ij} = N_i^* N_j^* \sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}, u_{ej}) + \sqrt{N_i^*} \sqrt{N_j^*} \sigma_{di} \sigma_{dj} \text{cov}(u_{di}, u_{dj}) + [1 - (1 - r_{mi})(1 - r_{mj})] N_i^* N_j^* \sigma_{oi} \sigma_{oj} \text{cov}(\overline{u_{oi}}, \overline{u_{oj}}). \quad (\text{A16})$$

Equation (A11) can be written as:

$$c_{ij} = a_i a_j c_{ij} + b_{ij}, \quad (A17)$$

which we can solve for c_{ij} :

$$c_{ij} = \frac{b_{ij}}{1 - a_i a_j}. \quad (A18)$$

The variance of community biomass, σ_{NT}^2 , is the sum of all the elements of the \mathbf{C} matrix:

$$\begin{aligned} \sigma_{NT}^2 &\approx \sum_{i,j=1}^S \frac{b_{ij}}{1 - a_i a_j} \\ &= \sum_{i,j=1}^S \frac{N_i^* N_j^* \sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}, u_{ej})}{1 - (1 - r_{mi})(1 - r_{mj})} + \sum_{i=1}^S \frac{N_i^* \sigma_{di}^2}{1 - (1 - r_{mi})^2} + \sum_{i,j=1}^S N_i^* N_j^* \sigma_{oi} \sigma_{oj} \text{cov}(\overline{u_{oi}}, \overline{u_{oj}}) \end{aligned} \quad (A19)$$

The first term in this equation is the contribution of environmental stochasticity, the second the contribution of demographic stochasticity, and the last the contribution of observation error. In practice, we do not know how the observation error between individual species in a community covary; assuming that observation error on each species is the same in monocultures and in mixtures, and that the covariances of observation error between species in mixture plots are independent, we get:

$$\sum_{i,j=1}^S N_i^* N_j^* \sigma_{oi} \sigma_{oj} \text{cov}(\overline{u_{oi}}, \overline{u_{oj}}) = \frac{\sum_{i=1}^S N_i^{*2} \sigma_{oi}^2}{n_x}, \quad (A20)$$

where σ_{oi}^2 is the observation error (variance of the log biomass between subsamples within plots and years) in monocultures of species i , and n_x is the number of subsamples taken within a plot within a year and used to estimate the CV of community biomass.

Finally, we obtain equation (3) by replacing the equilibrium abundances with the average abundance of species, $N_i^* = \overline{N_i}$ which is true in stationary state, and dividing by the

122 squared mean plot biomass to get our estimate of the squared CV of total community
 123 biomass:

$$\begin{aligned}
 CV_{NT}^2 &= \frac{\sigma_{NT}^2}{\overline{N_T}^2} \\
 124 \quad &\approx \sum_{i,j=1}^S \frac{\overline{p_i p_j \sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}, u_{ej})}}{1 - (1 - r_{mi})(1 - r_{mj})} + \frac{\sum_{i=1}^S \frac{\overline{p_i \sigma_{di}^2}}{1 - (1 - r_{mi})^2}}{\overline{N_T}} + \frac{\sum_{i=1}^S \overline{p_i}^2}{n_x} \frac{\sum_{i=1}^S \overline{p_i}^2 \sigma_{oi}^2}{\sum_{i=1}^S \overline{p_i}^2}. \quad (A21) \\
 &\approx \varphi_e \Sigma_e^2 + \frac{\Sigma_d^2}{\overline{N_T}} + \frac{\lambda \Sigma_o^2}{n_x}
 \end{aligned}$$

125 where $\overline{N_T}$ is mean total community biomass, and

$$126 \quad \varphi_e = \frac{\sum_{i,j=1}^S \frac{\overline{p_i p_j \sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}, u_{ej})}}{r_{mi} + r_{mj} - r_{mi} r_{mj}}}{\Sigma_e^2} \quad (A22)$$

127 is the synchrony of species environmental responses. This measure varies between 0
 128 when species are perfectly asynchronous, to 1 when species are perfectly synchronized.
 129 Perfect asynchrony between a pair of species requires that the positive environmental
 130 response in one species is perfectly counterbalanced by the negative environmental
 131 response of another species, taking into account their relative abundances. For example,
 132 perfect asynchrony between species 1 and 2 would require $u_{e1} = -u_{e2}$ and $p_1 \sigma_{e1} = p_2 \sigma_{e2}$
 133 : a response in an abundant species can only be counterbalanced by a stronger response in
 134 a species that is less abundant. Perfect synchrony on the other hand happens when
 135 $u_{ei} = u_{ej}$ for all i and j, leading to a maximal covariances between environmental
 136 responses: $\sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}, u_{ej}) = \sigma_{ei} \sigma_{ej}$, in which case the numerator in the synchrony in
 137 environmental responses equals the denominator. This synchrony measure generalises the

one derived by Loreau and de Mazancourt (2008) to cases where species differ in their parameters and relative abundances.

$$\Sigma_e^2 = \sum_{i,j=1}^S \frac{\overline{p_i p_j \sigma_{ei} \sigma_{ej}}}{r_{mi} + r_{mj} - r_{mi} r_{mj}} \quad (\text{A23})$$

is the mean scaled environmental variance,

$$\Sigma_d^2 = \sum_{i=1}^S \frac{\overline{p_i \sigma_{di}^2}}{1 - (1 - r_{mi})^2} \quad (\text{A24})$$

is the mean scaled demographic variance,

$$\lambda = \sum_{i=1}^S \overline{p_i}^2 \text{ is Simpson's concentration index (Simpson 1949)}$$

$$(\text{A25})$$

$$\Sigma_o^2 = \frac{\sum_{i=1}^S \overline{p_i}^2 \sigma_{oi}^2}{\sum_{i=1}^S \overline{p_i}^2} \quad (\text{A26})$$

is a mean observation variance,

$$\overline{p_i} = \frac{\overline{N_i}}{N_T} \text{ is species } i\text{'s observed average proportional biomass in the community, and } n_x$$

is the number of subsamples taken within plots and years used in the estimate of the CV of community biomass.

The environmental and demographic variances are scaled by a factor that depends on the species intrinsic growth rates, which determine the speed at which species return to equilibrium after a perturbation. Observation variance does not have that scaling because it does not affect community dynamics.

Simpson's concentration index is the complement of $1 - \lambda$, one of Simpson's diversity indices (Simpson 1949), which is affected both by species richness and evenness. Thus our formula suggests that species diversity (both higher richness and higher evenness) can decrease observation error. Regressions of the observed observation error versus Simpson's concentration index do indeed show such an effect (Cedar Creek: $R^2 = 0.07$, $P = 8e-4$; Jena: $R^2 = 0.02$, $P = 0.043$), but the higher explanatory power of our predicted observation variance indicates that there are strong species identity effects for observation error, especially in Jena (Fig. S3). In other words, observation error differed among species, and plots that contained species with high observation error exhibited greater observation error of community biomass.

Note that the squared coefficient of variation of community biomass depends directly on the mean environmental, demographic, and observation variances rather than these variances divided by the square of mean community biomass, because these variances are defined as variances of the growth rate of biomass on a log scale (Eq. 1) or of the log of community biomass (Eq. 2), making them scale-free in a way similar to a CV.

B. Materials and methods details

B.1. Simulation methods

We generated parameters for model (1) so that we could get coexisting communities with 6 species richness levels ($S=1, 2, 4, 8, 16$ and 32 species) and the synchrony of species environmental responses varied between zero and 1 at each species level (except for $S=1$, where by definition synchrony is 1).

Species carrying capacities, K_i , and interspecific competition coefficients, α_{ij} , were drawn until there was a potential equilibrium with all species present, i.e., $\mathbf{N}^* = \boldsymbol{\alpha}^{-1} \mathbf{K}$ had only positive elements. Carrying capacities were drawn from a lognormal distribution, i.e. $\ln(K_i)$ was drawn from a normal distribution with mean= $\ln(10,000)$, sd= 0.7 . The shape of the distribution corresponds to real grassland communities, where a typical mean value is around $\ln(500 \text{ g/m}^2)$ for the Jena experiment(Schmid *et al.* 2008). In the low connectance simulations, coexistence in diverse communities was ensured by a large number of zeros in the competition matrix(May 1973). The interspecific competition coefficients, α_{ij} , $i \neq j$, had a probability $C=0.0625$ to be non-zero, in which case they were drawn from a uniform distribution in the range $[0, 0.8]$. The large number of zeros resulted in overall low average levels of competition. In the high connectance simulations, coexistence in diverse communities was ensured by a low variance in the scaled competition coefficients, β_{ij} ,

where $\beta_{ij} = \alpha_{ij} \frac{K_j}{K_i}$ (Jansen & Kokkoris 2003). β_{ij} were drawn from a normal

distribution with standard deviation 0.02, and their means were one of 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8 or 0.9. Note that β_{ij} and β_{ji} were two parameters drawn independently,

so that competition could be asymmetric. Feasible communities without extinction were found up to $S=32$ and mean $\beta_{ij}=0.8$, so competition could be much higher on average than in low connectance simulations. In models like this, coexistence of competitors results in overyielding (i.e., a higher community biomass in species mixtures than in the average monoculture)(Loreau 2010).

Once a potential coexisting community was obtained, we drew the intrinsic rates of natural increase of each species, r_{mi} , from a uniform distribution in the range [0.2, 1.5] until the potential equilibrium was stable, i.e., the modulus of the dominant eigenvalue of the community matrix (the Jacobian at equilibrium) was less than 1.

For each of the two levels of connectance, we ran two sets of simulations, where either (a) environmental stochasticity or (b) demographic stochasticity was the main driver of community variability. Species demographic standard deviation, σ_{di} , were drawn from a uniform distribution in the range (a) [0, 2] and (b) [0, 4], while species environmental standard deviation σ_{ei} were drawn from a uniform distribution in the range (a) [0, 0.2] and (b) [0, 0.01].

Species i 's environmental response had the form:

$$\sigma_{ei}u_{ei}(t) = \sum_{j=1}^{n_E} e_{ij}u_j(t)$$

where $u_j(t)$ are random independent variables drawn from a standard normal distribution (mean=0, sd=1), and e_{ij} is species i 's specific response to environmental variable j . In order to simulate as wide a range of synchrony of species environmental responses as possible, we used $n_E=S$ random independent environmental variables(Loreau & de Mazancourt 2008), with values:

$$e_{ii} = \left(\beta - \frac{1}{S} \right) s_{ei}$$

$$e_{ij} = -\frac{s_{ei}}{S} \quad 1 \leq j \neq i \leq S$$

$$\text{where } s_{ei} = \frac{\sigma_{ei}}{\sqrt{\beta^2 - 2\frac{\beta}{S} + \frac{1}{S}}}$$

$$\beta = \frac{\varphi_e^{tar} - 1 + \sqrt{\varphi_e^{tar}(1 - \varphi_e^{tar})(S - 1)}}{S\varphi_e^{tar} - 1} \quad \text{if } \varphi_e^{tar} \neq \frac{1}{S}$$

$$\beta = 0.5 \quad \text{if } \varphi_e^{tar} = \frac{1}{S}$$

and φ_e^{tar} , the target synchrony in environmental responses, was chosen between 0 and 1.

With these relationships, $\sigma_{ei}^2 = \sum_{j=1}^{n_E} e_{ij}^2$, and

$$\sigma_{ei}\sigma_{ej}\text{cov}(u_{ei}, u_{ej}) = \sum_{k=1}^{n_E} e_{ik}e_{jk} = \sigma_{ei}\sigma_{ej} \frac{1 - 2\beta}{S\left(\beta^2 - 2\frac{\beta}{S} + \frac{1}{S}\right)}. \text{ As a result, the synchrony of}$$

species environmental responses varied between the minimum

$$\varphi_e^{\min} = \frac{\sum_{1 \leq i, j \leq S} N_i^* N_j^* \sigma_{ei} \sigma_{ej} \text{cov}(u_{ei}, u_{ej})}{\sum_{1 \leq i, j \leq S} N_i^* N_j^* \sigma_{ei} \sigma_{ej}} = \frac{\sum_{1 \leq i \leq S} N_i^{*2} \sigma_{ei}^2 - \sum_{1 \leq i \neq j \leq S} \frac{N_i^* N_j^* \sigma_{ei} \sigma_{ej}}{S - 1}}{\sum_{1 \leq i, j \leq S} N_i^* N_j^* \sigma_{ei} \sigma_{ej}}, \text{ and the maximum}$$

$$\varphi_e^{\max} = 1.$$

Once these parameters were chosen, community dynamics was simulated for 2,010 time-steps, with the expected average abundance of all species in the community, N_i^* , as initial conditions.

Realised communities were those where none of the species went extinct during the simulation. Time-steps 1,000-2,000 of the time-series were used to estimate the

characteristics of the community (mean community biomass and standard deviation) and of its component species in species mixture (mean biomass).

We simulated 1,000 single-species communities. For each of the other values of species richness ($S=2, 4, 8, 16, 32$), we generated 200 communities for each target level of species synchrony of environmental response (ϕ_e^{tar} , 11 values regularly spaced between 0 and 1). We repeated the simulations across the 2 levels of connectance, and 2 sets of values for environmental and demographic variances. This made a total of four sets of 12,000 simulated communities.

B.2. Field studies

The designs of the four biodiversity experiments used are summarized in Table S1 for ease of comparison.

The experiment at the Cedar Creek Ecosystem Science Reserve, Minnesota, USA, was established in 1994-1995 (Tilman *et al.* 2006). Land was treated with herbicide, burned, bulldozed, ploughed and harrowed in 1993 to clear extant plants and minimize the accumulated seed bank. Each of the 168 plots (9 x 9 m) was seeded in 1994 with 10g seed/m² and in 1995 with 5g seed/m², with this mass divided evenly between species randomly selected from an 18-species pool. Plots were burned annually, and included 1, 2, 4, 8, or 16 species. Species composition was maintained by hand weeding. Measurements used in our analysis were measurements of total aboveground biomass, collected all years, and species-specific biomasses, collected from 2000-2010. At each harvest, aboveground biomass was measured in 4 samples within each plot. During 1996-1999, each sample was 0.1 x 3 m; during 2000-2010, each sample was 0.1 x 6 m.

There were four complications in applying our methodology to these data. First, there were three species with non-replicated monocultures due to lack of seed

establishment: *Elymus canadensis*, *Poa pratensis* and *Panicum virgatum*. In these cases it was impossible to quantify demographic stochasticity, and thus we had to assume that it was zero. Secondly, oaks were excluded from our analysis (*Quercus ellipsoidalis* and *Quercus macrocarpa*) since their growth patterns differed qualitatively from that of the other vegetation, and two other species (*Elymus canadensis* and *Agropyron smithii*) were excluded because their monocultures became dominated by other species. This was accomplished by excluding all plots that were dominated by these species ($>50\text{g/m}^2$ average biomass for these species during 2000-2010) and ignoring their biomasses elsewhere. Findings are robust to the alternative methods of complete inclusion of all plots containing these species or their complete exclusion. Third, there were complications when *Petalostemum villosum* was sown in species mixtures. Due to seed contamination the legumes *P. villosum* and *P. candidum* were both sown in approximately equal densities in the 2-, 4-, and 8-species mixtures. Also, *Amorpha canescens* was sown instead of *P. villosum* in 16-species mixtures. Our analysis treats the biomass of these species as a single compound species. Fourth, due to the non-legume forb *Solidago rigida* not germinating in 1994, plots containing this plant were seeded with the non-legume forb *Monarda fistulosa* in 1995. *S. rigida* germinated the following year, hence all plots originally intended to be planted with *S. rigida* contained both species. Since we did not have their monoculture data, our analysis treats the biomass of these species as a single compound species.

The experiment near Wageningen, The Netherlands was established during 2000 (van Ruijven & Berendse 2007, 2009). In each plot, the topsoil was removed to a depth of 50 cm. Wooden frames were placed around the edges of these holes, which were 1 x 1 x 0.5 m (length x width x height), and each hole was filled with a mixture of pure sand and soil (3:1) from an old field. Seedlings were grown in a greenhouse, and 144 seedlings were transplanted into each 1 x 1 m plot in a substitutive design (i.e., same

density in all plots). The experiment consisted of 102 plots, planted in 6 blocks. Each block includes each of the 8 study species in monoculture, four 2-species mixtures, four 4-species mixtures, and the species mixture of all 8 species. No legumes were included in this study. Species composition was maintained by hand weeding. Our analysis includes aboveground biomass collected from 2000-2010. At each harvest, the 0.6 x 0.6 m interior of each plot was sampled.

The experiment near Temple, Texas, USA was established during 2001(Isbell *et al.* 2009). Seedlings were grown in a greenhouse, and 96 seedlings were transplanted into each 1 x 1 m plot in a substitutive design. The existing vegetation was removed with herbicide and the field was disked before planting. The experiment consisted of 75 plots in a formerly-cultivated field, planted in 3 blocks. Each block includes each of the 13 study species in monoculture, four 2-species mixtures, four 4-species mixtures, and four 8-species mixtures. No legumes were included in this study. Uniquely, two of each of the four mixtures of a given species richness in each block were established at maximal species evenness (i.e., equal planted proportions of species). The remaining 2 species mixtures of each richness level were established with realistically low species evenness (i.e., some species planted as dominant, and others planted as rare). Species composition was maintained by hand weeding. One species (*Oenothera speciosa*) was excluded from our analysis because it was lost from all plots during the second year of the study. Our analysis includes aboveground biomass collected from 2001-2010; however, species-specific parameters were based on 2001-2008 data, because several species were lost from all monocultures after 2008. At each harvest, the entire plot was sampled.

The experiment near Jena, Germany was established during 2002 in a former agricultural field(Proulx *et al.* 2010). Before sowing, the area was ploughed and kept fallow in 2001. In order to reduce weed pressure the field was harrowed bimonthly and treated with herbicide in July 2001. Each of the plots was seeded with 1000 viable

seeds/m². The main experiment consisted of 82 plots, each 20 x 20 m. This included 16 monocultures, 16 mixtures of 2, 4 and 8 species, 14 mixtures of 16 species, and four mixtures of all 60 species. Additionally, 120 monoculture plots, each 3.5 x 3.5 m, were established so that there were two replicate monocultures for each of the 60 study species. Half of the monocultures (i.e. 60 small plots) were given up in 2006. Plot size was reduced sequentially and is now 7x7 m and 1x1 m. All plots were distributed in 4 blocks. Species composition was maintained by hand weeding. We excluded 7 of the 60 species (i.e., *Ajuga reptans*, *Campanula patula*, *Cardamine pratensis*, *Luzula campestris*, *Trifolium campestre*, *T. dubium*, and *T. fragiferum*) from our analyses, due to lack of establishment or missing observations that prevented species parameter estimation. Our analysis included aboveground biomass collected twice per year (May and August) from 2003-2010; however, species-specific parameters were based on 2003-2006 data because only one of the replicate monocultures per species was maintained after 2006. Each harvest was treated as a separate time. At each harvest, aboveground biomass was measured in 4 samples for each large plot for 2002-2007; 3 for 2008-2009 and 2 in 2010, and 2 samples for each small monoculture plot. Each sample was 0.5 x 0.2 m.

B.3 Parameter estimation

Parameters were estimated for each species independently, using replicated monoculture data. Estimates of species carrying capacities, K_i , were obtained as the average biomass in monoculture (excluding the first year of experiments).

In monoculture j , we assume that species i follows simple dynamics given by:

$$r_i^{mono\ j}(t) = \ln N_i^{mono\ j}(t+1) - \ln N_i^{mono\ j}(t)$$

$$= r_{mi} \left[1 - \frac{N_i^{mono\ j}(t)}{K_i} \right] + \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{N_i^{mono\ j}(t)}} + \sigma_{oi} \left[\overline{u_{oi}(t+1)} + \left(r_{mi} \frac{N_i(t)}{K_i} - 1 \right) \overline{u_{oi}(t)} \right] \quad (B1)$$

328 Defining $x_i(t) = \ln(N_i^{mono j}(t)) - \ln(K_i)$, we derive a first-order approximation of observed
 329 biomass: $N_i^{mono j}(t) = \exp(\ln(N_i^{mono j}(t))) = \exp(\ln(K_i) + x_i(t)) \approx K_i(1 + x_i(t))$, and a first-
 330 order approximation of equation (B1):

$$\begin{aligned}
 331 \quad x_i(t+1) &\approx x_i(t) + r_{mi} \left[1 - \frac{K_i(1+x_i)}{K_i} \right] + \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{K_i}} + \sigma_{oi} [\overline{u_{oi}(t+1)} + (r_{mi} - 1) \overline{u_{oi}(t)}] \\
 &\approx (1 - r_{mi}) x_i(t) + \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{K_i}} + \sigma_{oi} [\overline{u_{oi}(t+1)} + (r_{mi} - 1) \overline{u_{oi}(t)}]
 \end{aligned}
 \tag{B2}$$

332 Without observation error, the first-order linear approximation of Equation (B1) is
 333 a first-order autoregressive process of the form $X(t) = ar(1)X(t-1) + e(t)$ (Box & Jenkins
 334 1970).

335 Observation error introduces a first-order moving average component to the error
 336 term, so it becomes an autoregressive moving average process of order 1,1, or
 337 ARMA(1,1), of the form: $X(t) = a[1]X(t-1) + e(t) + b[1]e(t-1)$ (Box & Jenkins 1970).

338 However, our time-series were much too short to give reliable estimates of both
 339 autoregressive and moving average components (Ives *et al.* 2003). We therefore made the
 340 assumption that $\sigma_{oi}(r_{mi} - 1) \overline{u_{oi}(t)}$ is small compared to $\sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{K_i}} + \sigma_{oi} \overline{u_{oi}(t+1)}$,
 341 and approximated equation (B2) as a simple first-order autoregressive process to estimate
 342 species intrinsic growth rate.

343 Species intrinsic growth rate parameters were thus obtained from the first-order
 344 autoregression coefficients of $\ln(N_i(t))$ where $N_i(t)$ is biomass in monoculture, taking
 345 the mean value over the replicate monocultures j : $r_{mi}^{est} = 1 - \overline{ar(1)_j}$. Estimates of
 346 autocorrelation coefficients are biased when estimating from short time-series, because of

temporal autocorrelation in the data, such that low values of r_m are overestimated (Box & Jenkins 1970).

Estimating environmental, demographic and observation variances

To estimate environmental, demographic and observation variances, we only used data from replicated monocultures. Defining $O_{ri}^x(t)$ as the observation error on the instantaneous species growth rate per unit biomass between time t and time $t+1$ on

sample x , $O_{ri}^x(t) = \sigma_{oi} \left[u_{oi}^x(t+1) + \left(r_{mi} \frac{N_i(t)}{K_i} - 1 \right) u_{oi}^x(t) \right]$, and assuming that the dynamics

follows equation (B1), with K_i and r_{mi} as estimated, in each plot, we have:

$$r_i^{x,j}(t) - r_{mi}^{est} \left[1 - \frac{N_i^j(t)}{K_i^{est}} \right] = \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{N_i^{mono j}(t)}} + O_{ri}^x(t) \quad (B3)$$

However, this relationship assumes that the mean is zero. To ensure that this is the case, and because we are interested in estimates of the variance per plot rather than the variance between plots, we removed the overall mean per plot:

$$stoch_i^{x,j}(t) = r_i^{x,j}(t) - r_{mi}^{est} \left[1 - \frac{N_i^j(t)}{K_i^{est}} \right] - mean_j \left(r_i^{x,j}(t) - r_{mi}^{est} \left[1 - \frac{N_i^j(t)}{K_i^{est}} \right] \right) \quad (B4)$$

where $mean_j$ is the mean of monoculture plot j .

$stoch_i^{x,j}(t)$ is thus the response variable whose variance components we want to estimate to estimate environmental and demographic variances:

$$stoch_i^{x,j}(t) = \sigma_{ei} u_{ei}(t) + \frac{\sigma_{di} u_{di}(t)}{\sqrt{N_i^{mono j}(t)}} + O_{ri}^x(t) \quad (B5)$$

We can use this relationship to estimate the environmental time-series $u_{ei}(t)$. An estimate of environmental stochasticity is the normalised mean across replicates and subsamples,

$$u_{ei}^{est}(t) = \frac{\overline{stoch_i(t)}}{sd(stoch_i(t))} \quad (\text{Table S2}). \quad \text{We partitioned the variation in } stoch_i^{x,j}(t) \text{ into three}$$

variance components (Table S2), which were then used to estimate environmental, demographic and observation variances of the intrinsic growth rate. Environmental variance, σ_{ei} , and the observation variance on the intrinsic growth rate, σ_{ori} , were estimated as indicated in Table S2. The standard deviation of demographic stochasticity was estimated from the plot variance as:

$$\sigma_{di} = \sqrt{K_i^{est} \sigma_{pi}^2} \quad (\text{B6})$$

Estimates of environmental or plot variance might happen to be negative (Nelder 1954). Negative values were found for 5 of the species in the Cedar Creek experiment and 12 of the species in the Jena experiment. We had to assume these variances were zero because we could not make the calculations with negative environmental variances: to compute the environmental term of equation 3 (Fig. 3), estimates of standard errors of component species are required (equations A22 and A23) and complex numbers could not be used. We thus cut the left tail of the distribution of estimates, thus introducing a bias that overestimates variances, a standard practice to cope with negative estimates of variance components.

Observation variance in the weighted mean observation variance term of Equation 3 is different from the observation error on the intrinsic growth rate, O_{ri} , in equations B3 and B5. The observation variance in our prediction is the variance of observation error on log biomass, σ_{oi}^2 (supporting online text equation A25). It was quantified as the variance

of the log biomass across samples taken within a monoculture plot within a year for species *i*.

B.4. Comparing predicted and observed quantities

To compare our prediction with observed community CV (Fig. 2), as well as to compare predicted observation variance with the observed observation variance (Fig. S3), major axis regression was performed with the lmodel2 package in R 2.11.1. Major axis regression is required to account for uncertainty in the explanatory variable (our prediction for community CV in Fig. 2 and our prediction for observation variance in Fig. S3). We also tested the extent to which our prediction explained variation in the observed community CV after accounting for richness (Table 1 and S3) and biomass by comparing nested models. Adding our prediction to the model that included richness and community biomass improved the fit (Cedar Creek: $F_{1,144} = 9.44$, $P = 2.5\text{e-}3$; Wageningen: $F_{1,99} = 3.52$, $P = 6.4\text{e-}2$; Jena: $F_{1,184} = 51.13$, $P = 2.0\text{e-}11$; Texas: $F_{1,69} = 67.13$, $P = 9.8\text{e-}12$), indicating that our prediction includes other important effects, such as species identity effects.

B.5. Explaining the observed CV using structural equation modeling

Two sets of structural equation models were developed and evaluated to examine factors contributing to observed variability (CV) in biomass (Figs. 3 and 4 in main text). In the first of these, the objective was to estimate the importances of the three additive components of equation (3), demographic stochasticity, environmental stochasticity, and observation error, in explaining observed variability. The second set estimated the degree

to which the individual components of equation (3) mediated the overall effect of species richness on observed variability. For all models, estimation was performed using lavaan, version 4 (Rosseel 2012) in R and using conventional evaluative criteria (Grace 2006). Data were examined for distributional properties and univariate relationships for linearity prior to modeling. All variables were logged prior to analysis. Case-wise deletion was used for missing values. Resulting sample sizes for the different datasets were as follows: Jena = 160; Wageningen = 102; Cedar Creek = 138; Texas = 72. Post-analysis diagnostics indicated reasonable distributions of errors. For the additive component models (Fig. 4) all models were saturated and had perfect data-model fit. For the mediation models (the second set, Fig. 5), errors among mediators were allowed to be freely intercorrelated in the initial model. Model simplification utilized single degree of freedom chi-square tests based on the model likelihoods. For these models, final model fit statistics were as follows: For Jena, model chi-square = 16.4 with 17 df and $p = 0.50$. For Wageningen, model chi-square = 8.6 with 7 df and $p = 0.28$. For Cedar Creek, model chi-square = 3.6 with 10 df and $p = 0.96$. For Texas, model chi-square = 3.4 with 7 df and $p = 0.85$. All of these results reflect close data-model fit. Overall, we judged the full-information maximum likelihood results to be robust based on model complexity, sample size, and diagnostics.

484 **Table S1 | Summary of the experimental designs of the four long-term grassland**485 **biodiversity experiments.** Notes: ⁿ¹ half of the monocultures (i.e. 60 small plots) were486 given up in 2006. ⁿ² plot size was reduced sequentially and is now 7x7 m and 1x1 m. ⁿ³487 only one 0.1 x 3 m sample sorted to species. ⁿ⁴ 4 in large plots for 2002–2007, 3 for

488 2008–2009 and 2 from 2010 onwards.

489

490 **Table S2 | Partitioning variance components**

Source	Sums of squares	Degrees of freedom	Mean square	Expected mean square	Estimated variance component
Time	$SS_y = n_x n_p \sum_{t=1}^{n_y} \left(\overline{stoch_i(t)} - \overline{stoch_i} \right)^2$	$df_y = n_y - 1$	$MS_y = SS_y / df_y$	$\sigma_{ori}^2 + n_x(\sigma_{pi}^2) + n_x n_p(\sigma_{ei}^2)$	$\sigma_{ei}^2 = (MS_y - MS_p) / n_x n_p$
Plot(Time)	$SS_p = n_x \sum_{t=1}^{n_y} \sum_{j=1}^{n_p} \left(\overline{stoch_i^j(t)} - \overline{stoch_i(t)} \right)^2$	$df_p = n_y n_p - n_p - df_y$	$MS_p = SS_p / df_p$	$\sigma_{ori}^2 + n_x(\sigma_{pi}^2)$	$\sigma_{pi}^2 = (MS_p - MS_x) / n_x$
Subsample(Plot(Time))	$SS_x = \sum_{t=1}^{n_y} \sum_{j=1}^{n_p} \sum_{x=1}^{n_x} \left(stoch_i^{x,j}(t) - \overline{stoch_i^j(t)} \right)^2$	$df_x = df_{Tot} - df_y - df_p$	$MS_x = SS_x / df_x$	σ_{ori}^2	$\sigma_{ori}^2 = MS_x$
Total	$SS_{Tot} = \sum_{t=1}^{n_y} \sum_{j=1}^{n_p} \sum_{x=1}^{n_x} \left(stoch_i^{x,j}(t) - \overline{stoch_i} \right)^2$	$df_{Tot} = n_y n_p n_x - n_p$			

491 Notes: $stoch_i^{x,j}(t)$ is the value from equation (B4) for subsample x in replicate monoculture plot j of species i at time t ; $\overline{stoch_i}$ is the
492 grand mean of all of these values across all n_x subsamples in all n_p monoculture plots during all n_y times for species i , which
493 equals zero; $\overline{stoch_i^j(t)}$ is the mean of these values across all n_x subsamples taken from monoculture j of species i at time t ; and
494 $\overline{stoch_i(t)}$ is the mean of these values across all n_x subsamples in all n_p monoculture plots of species i at time t . From these
495 values, we quantified environmental variance, σ_{ei}^2 , plot variance, σ_{pi}^2 , and the variance of observation error on the intrinsic
496 growth rate, σ_{ori}^2 , for each species i .

499

500 **Table S3 | Full model results**

Study	R ² (full model)	P (full model)	F (richness)	P (richness)	F (prediction)	P (prediction)
Cedar Creek	0.26	5.0e-4	F _{1,144} = 6.91	9.5e-3	F _{1,144} = 12.69	5.0e-4
Wageningen	0.41	1.8e-5	F _{1,99} = 19.19	2.9e-5	F _{1,99} = 20.30	1.8e-5
Jena	0.49	1.2e-17	F _{1,184} = 45.32	2.1e-10	F _{1,184} = 90.12	1.2e-17
Texas	0.77	1.6e-21	F _{1,69} = 4.67	3.4e-2	F _{1,69} = 190.26	1.6e-21

501 The full model included both the prediction and planted species richness as independent variables and the observed CV as the
502 dependent variable. R² and P-values are reported for the full model. Test statistics indicate whether adding planted richness to
503 the model that included the prediction (richness), or adding the prediction to the model that included planted richness
504 (prediction), significantly improved the fit.

Figure S1 | Simulated model communities: coefficient of variation of community biomass against the synchrony of species environmental responses, on a log-log scale. Left column: low connectance (low competition) communities; right column: high connectance (high competition) communities. Either environmental stochasticity (top row) or demographic stochasticity (bottom row) is the main driver of community variability. Each dot represents one community, colour indicates species richness. A sample of 1,200 out of the 12,000 simulated communities was plotted for clarity. Coloured solid lines represent the regression lines for each corresponding level of species richness, while the black solid line is the regression line pooling all levels of species richness together. If demographic stochasticity were negligible, the regression would have a slope of $\frac{1}{2}$, shown with the black dashed line.

Figure S2 | Simulated model communities: coefficient of variation of community biomass against community biomass (log of total biomass in grams). Left column: low connectance (low competition) communities; right column: high connectance (high competition) communities. Either environmental stochasticity (top row) or demographic stochasticity (bottom row) is the main driver of community variability. Each dot represents one community, colour indicates species richness. A sample of 1,200 out of the 12,000 simulated communities was plotted for clarity. Coloured solid lines represent the regression lines for each corresponding level of species richness, while the black solid line is the regression line pooling all levels of species richness together. If environmental stochasticity were negligible, the regression line would have a slope of $-\frac{1}{2}$, shown with the black dashed line.

Figure S3 | The predicted observation error was significantly correlated to its observed value in the two experiments with multiple samples per plot. R^2 and P -values are for major-axis regressions. Black dashed lines indicate 1:1 relationship. Grey lines

530 indicate 95% confidence interval for slope. Colours indicate number of planted or sown
531 species as in Fig. 2.
